Abstract. Malignant pleural mesothelioma (MPM) is an aggressive tumor of serosal surfaces with a poor prognosis. Methotrexate and gemcitabine have exhibited single-agent activity in MPM. We evaluated the feasibility of sequential administration of these agents in the treatment of MPM. A total of 21 patients with MPM received a 30-min infusion of 100 mg/m² methotrexate and, 30 min later, a 30-min infusion of 800 mg/m² gemcitabine. Twenty-four hours following the administration of methotrexate, leucovorin rescue therapy was initiated (10 mg/m² leucovorin administered 4 times at 6-h intervals). These treatments were administered weekly, with 4 weekly administrations constituting a cycle of therapy. A total of 88 cycles were administered to the 21 patients, with each patient receiving 1-10 cycles (median, 4.2 cycles). Eight patients (38.1%) exhibited a partial response, 10 patients (47.6%) had stable disease and 3 patients (14.3%) had progressive disease. The median overall survival was 19.4 months (range, 02-41 months). One-year and 2-year survival rates were 61.9 and 38.1%, respectively. Hematological toxicity was considered acceptable, with grade 3-4 toxicities occurring in 3 (14.3%) patients. Non-hematological toxicity was generally mild. There was no treatment-related mortality. Our results suggest that methotrexate and gemcitabine combination therapy is feasible and effective in the treatment of MPM. This regimen may offer an alternative to platinum-based chemotherapy and a prospective trial including a larger cohort of patients is recommended to confirm these results.

Introduction

Malignant pleural mesothelioma (MPM) arises from the mesothelial surface of the pleural cavity and is a locally invasive tumor with poor prognosis (1, 2). In >70% of patients, the tumor is associated with exposure to asbestos fibers following a long latent period of 20-50 years (3). The incidence of mesothelioma is rare in the general population; however, it is expected to increase in the next 20 years in industrialized countries as a result of past asbestos use (4, 5).

MPM is refractory to the currently available treatment options. The efficacy of surgical therapy has not been precisely defined (6) and radiotherapy may be palliative but does not prolong survival (7). For the majority of patients with MPM, systemic chemotherapy remains the standard of care (8). Prior to 2003, the majority of studies on chemotherapy for MPM were conducted using either single agents or combination regimens in the setting of small phase II trials. The results demonstrated <20% of tumor regression with no significant effect on patient survival, which was 6-9 months (8, 9). Since 2003, the combination of cisplatin and pemetrexed (PTX) has been used as standard chemotherapy for MPM (10). This was based on a randomized phase III study in which PTX plus cisplatin achieved a response rate of 41.3% and a median survival of 12.1 months, compared to 16.7% response rate and 9.3-month median survival achieved by cisplatin alone (10).

In this study, a non-platinum-based combination therapy with two anti-metabolites (methotrexate and gemcitabine) was devised. Methotrexate is an analogue of folic acid known to be effective against breast cancer, lymphoblastic leukemia and osteosarcoma (11, 12). Gemcitabine is a pyrimidine analogue, effective against a wide range of solid tumors, including pancreatic carcinoma and non-small cell lung carcinoma (13). Methotrexate and gemcitabine have been reported to exhibit single-agent activity in MPM (8, 9); however, the combined administration of these agents has not yet been investigated.

In the present study, we evaluated the feasibility and efficacy of methotrexate and gemcitabine combination therapy in the treatment of MPM, through the analysis of toxicity, response and survival data.

Patients and methods

Patients. Patients with histologically confirmed MPM who had previously received 0-1 chemotherapy cycles, not including gemcitabine and methotrexate, were considered eligible for this single-center study. Tumor extension was classified according to the tumor-node-metastasis (TNM) staging system developed by the International Mesothelioma Interest Group (IMIG) (14). Patients were 18-75 years of age, with an Eastern Cooperative Oncology Group (ECOG) performance status of 0-2, had adequate bone marrow function (hemoglobin concentration ≥10 g/dl, total leukocyte count ≥3.0x10⁹/l, granulocyte count ≥1.5x10⁹/l, and platelet count ≥100x10⁹/l), adequate renal function (serum creatinine level <1.5 mg/dl) and adequate hepatic function (total bilirubin level ≤1.5 times the upper limit of normal). Patients were considered eligible for this study if they had signs of metastases in the central nervous system were excluded. Patients with a concurrent malignancy of another type or symptoms and/or signs of metastases in the central nervous system were excluded. Patients with prior surgery were considered eligible. This study was approved by the Institutional Review Board of Hyogo College of Medicine and informed consent was obtained from each patient.

Treatment. Patients received a 30-min intravenous (i.v.) infusion of 100 mg/m² methotrexate and, 30 min later, a 30-min i.v. infusion of 800 mg/m² gemcitabine. For leucovorin rescue, calcium leucovorin (10 mg/m², p.o. or i.v.) was administered 4 times at 6-h intervals, initiated 24 h after the administration of methotrexate. These treatments were administered weekly, with 4 treatments constituting a cycle of therapy. A maximum of 6 cycles were administered, unless therapy was terminated due to tumor progression, patient death or wish of treatment discontinuation, or in the presence of convincing evidence that further treatment was not beneficial. Antiemetic and symptomatic treatments were permitted. Analyses of blood cell count and chemistry were performed weekly. Treatment was delayed in the case of (i) absolute neutrophil count <1.5x10⁹/l and/or platelet count <100x10⁹/l; (ii) any grade 3 or 4 non-hematological toxicity (except for nausea/vomiting) that did not resolve to grade 1 or less. If these toxicities were not resolved within the cycle, the dose was reduced to 75% of the previous dose level for the next cycle.

Response and toxicity criteria. Chest imaging by computed tomography (CT) was performed at baseline, following completion of every other treatment cycle and every 8 weeks following completion of therapy. Objective response was evaluated and calculated using the modified Response Evaluation Criteria in Solid Tumors (RESIST) criteria for MPM (15). Treatment-related toxicities were evaluated according to the National Cancer Institute Common Toxicity Criteria version 3.0 (16).

Statistical analysis. Survival was calculated as the time period from treatment initiation to death, using the Kaplan-Meier method (17).

Results

Patient characteristics. The characteristics of the 21 eligible patients are listed in Table I. There were 16 males and 5 females, with a median age of 63 years (range, 51-75 years). The histological pattern of MPM was epithelial in 17 cases, sarcomatous in 3 cases and biphasic in 1 case. Nineteen patients (90.4%) had stage III and IV disease according to the IMIG staging system at the time of enrollment. Thirteen patients (61.9%) had an ECOG performance status of 0 or 1.

Responses to treatment. A total of 88 cycles were administered to the 21 patients. Each patient received a median 4.2 cycles (range, 2-10 cycles). Response to chemotherapy is shown in Table II. No patients exhibited a complete response. Eight patients (38.1%) exhibited a partial response. According to the histological pattern, a PR was observed in 6 of the 17 patients with epithelial type and in 2 of the 3 patients with sarcomatous type MPM. Out of the total 21 patients, 10 (47.6%) had stable disease and 3 (14.3%) had progressive disease with no period of stabilization.

Toxicity. The toxicity observed in each patient is shown in Table III. There was no treatment-related mortality. The most frequently observed hematological side effects were neutropenia and thrombocytopenia. Grade 3-4 hematologic
toxicities were observed in 3 patients (14.3%), which, however, were manageable and did not result in life-threatening complications. Six patients (28.6%) experienced grade 1-2 gastrointestinal toxicities (nausea, vomiting and anorexia) and 7 patients (33.3%) developed grade 1-2 liver dysfunction. Two patients developed interstitial pneumonitis (grade 2) and were administered glucocorticosteroid therapy.

Survival. The median overall survival was 19.4 months (range, 2-41 months), with a 1- and 2-year survival rates of 61.9 and 38.1%, respectively (Fig. 1). As regards the histological pattern, the median survival was 19.6 months for the epithelial, 22.6 months for the sarcomatous and 7.1 months for the biphasic type of MPM.

Discussion

MPM is notoriously refractory to the majority of treatments and the standard first-line treatment is currently cisplatin and PTX chemotherapy (10). In the present study, we evaluated the feasibility of a non-platinum regimen for MPM, involving the sequential administration of the anti-metabolites, methotrexate and gemcitabine.

Methotrexate, an antifolate, has long been used as an anticancer agent and exerts its action through the inhibition of dihydrofolate reductase (DHFR) (12). High-dose methotrexate (1500 mg/m²) has been reported to be effective in the treatment of MPM, with a response rate of 37% (18). However, high-dose methotrexate was associated with severe toxicity and this method of treatment has been abandoned. The efficacy of low- or medium-dose methotrexate has not been assessed in MPM. In the treatment of gastric cancer (19) and head and neck cancer (20), weekly administration of medium-dose methotrexate (100-200 mg/m²) combined with sequential administration of 5-fluorouracil (5-FU) (600 mg/m²) has been reported to be effective and of low toxicity. In this study, a moderate dose of methotrexate (100 mg/m²) was administered weekly in combination with gemcitabine.

PTX is a newly developed antifolate that targets multiple enzymes involved in DNA synthesis and folate metabolism. Single use of PTX has been reported to be moderately effective against MPM (21). Following combination therapy with 1,250 mg/m² gemcitabine administered on days 1 and 8 and 500 mg/m² PTX administered on day 8 or 1, chemotherapy-naïve MPM patients exhibited a response rate of 17-26%, with a median survival of 8-10 months (22). Hematologic toxicities included grade 3-4 neutropenia (60%) and febrile neutropenia (10%). These results indicated that the combination of PTX and gemcitabine was moderately effective in MPM patients but was associated with a notably high incidence of neutropenia (22).

In this study on the methotrexate and gemcitabine doublet regimen, 3 patients (14.3%) exhibited grade 3-4 hematologic toxicity, with no sepsis or hemorrhage. There was no observed grade 3-4 non-hematologic toxicity. Two patients developed interstitial pneumonitis (grade 2) which responded well to
steroid therapy. Thus, the tolerability and toxicity profiles were considered acceptable.

The response rate with the methotrexate and gemcitabine combination chemotherapy was 38.1%, which is within the range of 20-50% observed with other ‘active’ agents for MPM (8,10). Median survival was 19.4 months. Antifolates may be one of the key agents for MPM, since the majority of mesothelioma cells of all histological MPM subtypes express high-affinity α folate receptor (23). In our combination regimen, we observed that methotrexate, an old-type antifolate, exhibited desirable efficacy. Methotrexate has also been reported to be more efficient compared to PTX, a newly developed antifolate, against osteosarcoma cells (24), indicating that methotrexate possesses a therapeutic potential.

In the present study, 10 out of the 21 patients were chemotherapy-naïve and their response rate to this regimen was similar to the overall response rate described above. This suggests that methotrexate plus gemcitabine may be beneficial as the first-line treatment for MPM. Eleven patients who had been previously treated also exhibited a response rate similar to the overall response rate. Although the optimal regimen constituting the second-line chemotherapy remains to be determined, results of the present study suggest that methotrexate plus gemcitabine may also be beneficial as a second-line treatment.

In conclusion, the present study demonstrated that the methotrexate and gemcitabine combination therapy is feasible, with a more favorable toxicity profile and efficient in the treatment of MPM. Further clinical evaluation is required, with prospective trials including a larger cohort of patients.
